Executive Summary
The Oregon Department of Transportation (ODOT) is exploring a method of ball-banking highway curves that promises to be more time and cost effective and safer for investigators than the current method of ball-banking.

In recent years, ODOT has produced spreadsheet software to aid ball-bank data collection, but the data collection process has largely remained the same. Investigators still need to drive through curves multiple times to determine maximum recommended speeds. For experienced investigators, this process can take 30 to 90 minutes per curve. A method to streamline the data collection process would greatly reduce labor costs and safety risks associated with curve evaluations.

The Rieker Curve Advisory Reporting System (CARS) promotes successful data collection with one pass in each direction, with traffic, at any speed. Before replacing traditional data collection statewide with CARS, ODOT Traffic-Roadway and Region 2 Traffic conducted basic shakedown testing of the Rieker system in the summer of 2014. This technical white paper documents the shakedown testing and helps inform how curves should be analyzed on ODOT highways using CARS.

Based on the analysis and findings of this investigation, the following can be concluded and recommended:

- The CARS methodology uses best-fit models and common design equations from the Green Book and is an acceptable method to determine curve advisory speed.
- CARS and the ODOT spreadsheet recommended advisory speeds are generally within 5 mph of each other. When different, CARS tends to recommend advisory speeds greater than the ODOT spreadsheet, within 5 mph .
- For statewide consistency, all Oregon highways should be evaluated using the CARS methodology.
- An inexperienced investigator can achieve similar results to an experienced investigator if properly trained and with some practice.
- Speed from run to run on the same curve does not need to be constant.
- When driving through a curve, speed should be kept relatively constant to avoid unnecessary spikes in lateral acceleration.
- Greater model fits generally result in more precise estimates of advisory speed. When building curves, strive for a fit of $99 \%$ or better; $96 \%$ or better is sufficient.
- The average calculated advisory speed of 3 runs should be used when determining the final advisory speed. If data are collected properly, this average should be within $\pm 3.5 \%$ of the true average at the $95 \%$ confidence level.
- A training class for traffic investigators and sign designers should be developed for statewide consistency.

## Introduction

In an effort to be more consistent determining curve advisory speeds, the Oregon Department of Transportation (ODOT) is exploring a method of ball-banking highway curves that promises to be more time and cost effective and safer for investigators than the current method of ball-banking.

The current accepted curve advisory speed evaluation method is ball-banking [1]. In recent years, ODOT has produced spreadsheet software to aid ball-bank data collection, but the basic ball-banking method has largely remained the same. Investigators still need to drive through the curve multiple times to determine the maximum advisory speed. If that speed is different than the current advisory speed, the investigator needs to drive through the curve 3 times in each direction at that speed in order to change the advisory speed. For experienced investigators, this process can take 30 to 90 minutes per curve, depending on availability of safe turn-around points, accuracy of existing signing, and traffic volumes during the investigation, among other variables. Because of this duration, remote locations can require overnight accommodations for investigators. A method to streamline the data collection process would greatly reduce labor costs and safety risks associated with curve evaluations.

Rieker, Inc. approached ODOT in the spring of 2014 with their new Curve Advisory Reporting System (CARS), promoting successful data collection with one pass in each direction, with traffic, at any speed using the accepted ball-banking method. Before replacing data collection strategies statewide with CARS, ODOT Traffic-Roadway and Region 2 Traffic conducted basic shakedown testing of the Rieker system in the summer of 2014; more statistically relevant results can be achieved by examining a larger, more diverse dataset. This technical white paper documents the shakedown testing and helps inform how curves should be investigated on ODOT highways using CARS.

## Scope

The scope of this white paper was to:

- determine how the Rieker tool calculates curve advisory speeds,
- test sensitivity of results based on different driving methods and number of runs,
- compare advisory speed recommendations from the ODOT Spreadsheet to CARS, and
- develop recommendations on if and how ODOT will use the CARS tool.

Recommendations needed to be completed by fall 2014 to allow investigators to begin collecting data and curves analyzed as soon as practical for project development and delivery, pursuant the December 31, 2019 MUTCD compliance date for horizontal alignment signs [2]. More statistically relevant results can be achieved by examining a larger, more diverse dataset. This could be achieved through a more formalized research project.

## MUTCD Advisory Speeds

Ball-banking limits used by ODOT in the past were lower than the 2009 MUTCD limits. Limits currently accepted for use in Oregon are found in the 2009 MUTCD [1]. These higher limits better meet expected driver performance through horizontal curves as research has shown drivers often exceed curve advisory speeds by 7 to 10 mph [2]. Dixon and Rohani [3] and Dixon and Avelar [4] provide some history of this transition in Oregon in their reports.

Section 2C. 08 of the 2009 MUTCD [2] says "the advisory speed shall be determined by an engineering study that follows established engineering practices." Among the engineering practices listed as appropriate for the determination of the recommended advisory speed for a horizontal curve is a traditional ball-bank indicator using the following criteria:

1. 16 degrees of ball-bank for speeds of 20 mph or less
2. 14 degrees of ball-bank for speeds of 25 to 30 mph
3. 12 degrees of ball-bank for speeds of 35 mph and higher.

Section 2C. 08 goes on to say "the 16, 14, and 12 degrees of ball-bank criteria are comparable to the current AASHTO horizontal curve design guidance. Research has shown that drivers often exceed existing posted advisory curve speeds by 7 to 10 mph ."

Currently, the curve reports generated through the CARS Portal will default the MUTCD limit corresponding to the posted regulatory speed entered by the user. Ball-banking practice published in Oregon, several other states, FHWA's Safety Website, and ITE's Traffic Control Devices Handbook ( [5], [6], [7], [8], [9], [10], [11]) use the MUTCD limit corresponding to the speed of the test run during investigation. In the absence of a regulatory speed, the system will default to 12 degrees. The MUTCD limits need to be manually entered on slower curves ( $<35 \mathrm{mph}$ calculated advisory speed) to make sure the correct limit is being used.

## Kinematics

An analysis of the forces acting on a vehicle traveling through a curve is shown in Figure 1 [12]. This analysis ignores the small effects of body-roll (see Body Roll Rate discussion) and assumes the digital inclinometer instrument is properly mounted in the vehicle and properly leveled.

Where:
$\varphi=$ Superelevation Angle
$\alpha=$ Inclination, or "Ball-bank" angle
$v=$ vehicle speed
$R=$ curve radius
$N=$ normal force
$f=$ side friction factor
$g=$ gravitational acceleration
(not to scale)

Figure 1 | Geometry of Forces Acting on Vehicle
(ignoring the effects of body roll)

## Inclination

The RDS7-GPS-PRO is an accelerometer built to display degrees of inclination. The angle displayed on the instrument is the angle of the Resultant Force $F_{R}$ the accelerometer is measuring relative to itself (theoretically, relative to the highway surface). When traversing a curve, this is the force that results from adding the gravitational force vector and the "centrifugal force" vector.

For example, when the instrument is not moving and on a level pad, the only force acting on it is gravity. This force is perpendicular to the instrument, so zero degrees is displayed. When the instrument is moving around a curve, the instrument is measuring the resultant force of gravity and centripetal acceleration. The angle of this resultant force relative to the instrument is the inclination angle displayed by the instrument.

Note the "centrifugal force" is not a real force - it's actually the feeling of a force resulting from inertia because the vehicle wants to continue moving in a straight line tangent to the curve. "Centrifugal force" and centrepital force are calculated using the same formula, $F=m a_{c}=m\left(v^{2} / R\right)$.

## Body Roll Rate

Body roll rate is calculated:

$$
R_{\Phi}=\frac{m_{s} g h_{1}}{K_{s}-m_{s} g h_{1}}
$$

Where:
$R_{\Phi}=$ roll rate of body ( $\mathrm{rad} / \mathrm{g}$ )
$m_{s}=$ mass of sprung vehicle including suspension members
$g=$ gravitational acceleration ( $32.2 \mathrm{ft} / \mathrm{s}^{2}$ )
$h_{l}=$ vertical difference between the roll axis and the center of mass of sprung mass
$K_{s}=$ suspension roll stiffness ( $\mathrm{N}-\mathrm{m} / \mathrm{rad}$ )
Carlson and Mason [13] investigated the effect body roll rate has on ball-bank indicator readings and resulting advisory speeds. Typical passenger vehicles at the time of the report (1992) had a body roll rate that ranged between 3 and 7 degrees $/ \mathrm{g}$ ( 7 degrees being typical of a 1992 Ford Taurus). At a 10 degree ball bank indicator angle, the error due to body roll would range between 0.5 and 1.2 degrees. At a 14 degree reading, the error would be 0.7 to 1.7 degrees.

The error due to body roll increases the reading of the ball bank indicator (that is, the more the vehicle rolls, the greater the ball bank reading). If the body roll is neglected, then the determined advisory speed would be slightly lower than the theoretically correct comfortable speed. The magnitude of the difference would depend on the roll rate of the test vehicle, the unbalanced lateral acceleration acting on the vehicle, the radius, and the superelevation. Carlson and Mason found if a vehicle with a roll rate of 7 degrees $/ \mathrm{g}$ were used to determine safe speed on a horizontal curve and that roll rate were neglected, the estimated safe speed would be 5 to 7 percent less than intended. For cars with a roll rate less than 7 degrees $/ \mathrm{g}$, the difference would be even less. Carlson and Mason concluded that although the body-roll influences the reading of the ball-bank indicator somewhat, it does not greatly affect the posting of comfortable horizontal curve speeds.

For example, if the estimated advisory speed were 55 mph , the theoretically correct advisory speed would be approximately 3.9 mph higher, assuming a 7 percent difference.

Based on Carlson's and Mason's findings, if a typical passenger vehicle is used to investigate curve advisory speeds, the effect of body roll may be neglected. In the $20+$ years since this study, passenger vehicle body roll rates have likely decreased as vehicle handling performance has improved, such as Electronic Stability Control systems. Therefore, neglecting the body roll effect while using passenger vehicles is still likely appropriate for traditional ball-banking.

## Equations

From the geometry of the forces shown in Figure 1, the following can be defined:

$$
\begin{gathered}
\text { Resultant Force, } F_{R}=\sqrt{(m g)^{2}+\left(m \frac{v^{2}}{R}\right)^{2}} \\
\text { Normal Force, } N=F_{R} \cos (\alpha) \\
\text { Friction Force, } F_{f}=f N \\
\left(f=\text { side friction demand factor }, f_{D}\right)
\end{gathered}
$$

## Equation 1

Equation 2

Equation 3

In order for the vehicle's tires to resist skidding, the "centrifugal force" must be resisted by the available friction between the tires and the road surface. This friction force is the normal force multiplied by the side friction demand factor, $f_{D}$. If the highway surface is the x -axis, and the tires are not skidding to the outside of the curve, the forces along the x -axis must balance. Equation 4 results when the forces along the x -axis are solved for side friction demand (Equation 4 is an approximation due to ignoring the effects of body roll):

$$
\begin{gathered}
\sum F_{x}=0=F_{R} \sin (\alpha)-f_{D} N \\
F_{R} \sin (\alpha)=f_{D} F_{R} \cos (\alpha) \\
f_{D}=\frac{\sin (\alpha)}{\cos (\alpha)} \\
f_{D} \approx \tan (\alpha)
\end{gathered}
$$

## Equation 4

Note the RDS7-BB-PRO differentiates between left and right directionality by assigning positive and negative inclination. At normal run speeds, where the resultant force shown in Figure 1 is towards the outside of the curve, friction demand is keeping the vehicle from sliding to the outside of the curve. The way the following equations are set up assumes this is positive friction demand.

When run speeds are very slow, resulting in nominal centrepital acceleration, and if superelevation is present, side friction acts in an opposite direction to keep the vehicle from sliding to the inside of the curve. The resultant force in Figure 1 is then towards the center of the curve. This inward direction is opposite that shown in Figure 1 and represents a negative value for friction demand. The sign of the inclination angle used in Equation 4 is determined using the following rules [12]:

- Inclination is negative ( - ) if the inclination angle is:
- To the right of 0.0 degrees on a right-hand curve
- To the left of 0.0 degrees on a left-hand curve
- Inclination is positive $(+)$ if the inclination angle is:
- To the left of 0.0 degrees on a right-hand curve
- To the right of 0.0 degrees on a left-hand curve

The resulting side friction demand factor limits set by the MUTCD are given in Table 1, calculated using Equation 4, rounded down to the nearest $0.01 \mathrm{ft} / \mathrm{ft}$.

Table 1 | MUTCD Side Friction Limits

| MUTCD Ball-Bank Angle Limit | Side Friction Demand Limit |
| :---: | :---: |
| 12 degrees | 0.21 |
| 14 degrees | 0.24 |
| 16 degrees | 0.28 |

From the AASHTO Green Book, the simplified curve formula solved for side friction is:

$$
f_{D}=\frac{\left(1.47 V_{c}\right)^{2}}{g R}-\frac{e}{100}
$$

Equation 5
where,
$f_{D}=$ side friction demand factor (or lateral acceleration);
$e=$ superelevation rate, percent;
$V_{c}=$ curve speed, mph;
$g=$ gravitational acceleration ( $=32.2 \mathrm{ft} / \mathrm{s}^{2}$ ); and
$R=$ radius of curve, ft .

In order to estimate the speed at a side friction limit, ball-bank angle, vehicle speed, and vehicle position must be known. The vehicle position over time can be used to estimate curve radius. With these known variables, superelevation can be calculated by solving Equation 5 for superelevation:

$$
e=100\left[\frac{\left(1.47 V_{c}\right)^{2}}{g R}-f_{D}\right]
$$

Once superelevation is known, the MUTCD side friction limits from Table 1 can be entered as $f_{D}$ to determine the speed the limits will be reached. Equation 5 can be solved for vehicle speed:

$$
V_{c}=\frac{\sqrt{g R\left(f_{D}+\frac{e}{100}\right)}}{1.47}
$$

## Variables

The Kinematics section discussed which variables are needed and how those variables are used to calculate an advisory speed. This section discusses how CARS calculates each variable. An example calculation walk-through is available at the end of the Appendix.

## Inclination

The RDS7-GPS-PRO measures inclination several times each second. Because of the frequency and precision of measurement, these data can be "noisy" and must be post-processed to give a meaningful inclination measurement for advisory speed calculation.

Below are comparisons of raw inclination data and the normalized data from a CARS report. These data were collected by ODOT Region 2's Weldon Ryan on Silver Falls Highway on June 3, 2014 and Three Rivers Highway on June 4, 2014. The blue diamonds are the reported inclination in the raw run data reported directly from the inclinometer. The red squares are the modeled data reported in the curve evaluation report. Both of these datasets were fit with a best-fit model in Excel to confirm the model CARS is using is a best-fit parabola.

From these results, the modeled inclination, or "measured side friction," reported by CARS are normalized inclination data using a second-order polynomial best fit curve (parabola) through the raw inclination readings. The resulting normalized inclination curve is used to calculate demanded side friction to calculate superelevation (see Kinematics section).

It is important to check the curve report to make sure the inclination curve is a parabola with a clear maximum or minimum that is not at either end, even if the report "fit" is very good. If the inclination curve does not show a maximum or minimum, the critical area of the curve probably has not been included in the "net"; increasing the dataset usually results in a clear maximum or minimum.

## Speed

CARS measures vehicle speed from the GPS roughly every 0.3 seconds [14]. Because of the frequency of measurement, and because the GPS unit is not survey-grade, driving speed through the curve is post processed to give a meaningful speed measurement for advisory speed calculation.

Below are comparisons of raw speed data and the normalized data reported by the CARS curve report. These data were collected by ODOT Region 2's Weldon Ryan on Silver Falls Highway and Three Rivers Highway. The curve reports are available upon request.

The blue diamonds are the reported speed in the raw run data, reported directly from the GPS. The red squares are the modeled data reported in the curve evaluation report. Both of these datasets were fit with a best-fit model to confirm the model CARS is using is a best-fit parabola.

From these results, the modeled speed, or "test speed," reported by CARS are normalized speed data using a second-order polynomial best fit curve (parabola) through the raw vehicle speed readings. The resulting normalized speed curve is used to calculate superelevation (see Kinematics section).

## Radius

CARS records location (lat/long) from the GPS roughly every 0.3 seconds [14]. These data are used to calculate the curve radius used to calculate advisory speed. Because of the frequency of measurement, and because the GPS unit is not survey-grade, location data are post processed to give a meaningful radius estimate for advisory speed calculation.

During post processing, individual location points are plotted relative to the Point of Curvature, PC (i.e., the PC is at $(0,0))$ by converting latitude and longitude into Cartesian ( $\mathrm{x}, \mathrm{y}$ ) coordinates using the Universal Transverse Mercator geographic coordinate system [14]. The Defense Mapping Agency (now called the National Geospatial-Intelligence Agency) discusses the calculations required to complete this conversion in their report The Universal Grids: Universal Transverse Mercator (UTM) and Universal Polar Stereographic (UPS) [15]. There are many online applications that complete these calculations with mapping features.

Once individual location points are plotted, parabolic models are fit to the change in latitude over time and longitude over time to estimate the path the investigation vehicle traveled around the curve. This results in two dependent variables $-x$ and $y-$ and one independent variable - time. When these points are combined, it results in a parabola oriented to match the investigation vehicle's path.

To confirm this, raw lat/long data were plotted from data collected by Weldon Ryan on Mist-Clatskanie Highway and compared to the Modeled $x$ and $y$ points given in the curve report. The Modeled $x$ and $y$ points matched the parabola fit to the raw lat/long data when the PC was set to coordinates $(0,0)$.

When these data were laid over a Google aerial view of the curve, the best-fit line and CARS modeled coordinates matched the vehicle path through the curve very well $\left(\mathrm{r}^{2}>0.99\right)$, shown in Figure 2. The black points are the raw lat/long coordinates, white points are the CARS Modeled $x$ and $y$ coordinates, and the red points are the calculated coordinates based on the best-fit x and y models shown in the graph. The calculated radius at the modeled apex was 147 feet, very close to the ODOT Horizontal Curve Report radius of 143 feet ( 40 degree curve). The calculated radius was the same as the reported minimum radius in the CARS report.

Figure 2 | Raw and Modeled Location Data over Aerial Map

It is important to note horizontal curves are circular curves, usually with spiral curves on the ends - not a parabola. For the purpose of estimating curve shape for advisory speeds, a parabolic model fits the vehicle path data well (if the data are selected appropriately, $\mathrm{R}^{2}>0.96$ ), so curve shape estimates should be close to real-world vehicle path shape.

In order to estimate the radius of the curve along the path of travel, CARS calculates the radius of curvature along the parabolic shape of the modeled curve. For each point along a parabola, the radius of curvature can be calculated to determine the radius of the approximating circle at that point. The formula for radius of curvature at any point $x$ for the curve $y=f(x)$ is given in Equation 8. Another method to determine radius at a point is the 3-Point Method. For clarity, the following discussion will use the radius of curvature equation.

$$
\begin{equation*}
\text { Radius of Curvature, } R=\frac{\left[1+\left(\frac{d y}{d x}\right)^{2}\right]^{\frac{3}{2}}}{\left|\frac{d^{2} y}{d x^{2}}\right|} \tag{Equation 8}
\end{equation*}
$$

A good explanation and interactive exercise on the concept of Radius of Curvature can be found at intmath.com. Since the curve model is a parabola, finding the first and second derivative for the curve is simple. In order to verify reported radii using Excel's graphing functions, the modeled parabola must be rotated so the directrix is parallel with the x -axis (i.e.: so the parabola is symmetrical about the y -axis to determine the curve's equation). Parabolas can be rotated if any 4 points $P, Q, R, S$ along the curve are known [16], shown in Figure 3.

Figure 3 | Parabola through Four Points
From the geometry shown in Figure 3, the following properties can be defined:
$r_{l}=$ length of ray PR
$r_{2}=$ length of ray QR
$r_{4}=$ Length of ray SR
$\alpha=$ angle between rays RQ and RS
$\beta=$ angle between rays PR and SR
$\gamma=$ counter-clockwise angle between ray $\operatorname{SR}$ and the positive x -axis
$\theta=$ angle between ray SR and the directrix
$\omega=$ parabola rotation angle
The angle between the ray SR and the directrix, $\theta$ can be determined by solving Equation 9 for $\theta$ :

$$
A \tan (\theta)^{2}+B \tan (\theta)+C=0
$$

Equation 9
Where:

$$
\begin{aligned}
& A=\sin \alpha \sin \beta\left(\sin \alpha r_{2}-\sin \beta r_{1}\right) \\
& B=2 \sin \alpha \sin \beta\left(\cos \beta r_{1}-\cos \alpha r_{2}\right) \\
& C=\sin \alpha \cos \beta\left(r_{4}-\cos \beta r_{1}\right)-\sin \beta \cos \alpha\left(r_{4}-\cos \alpha r_{2}\right) \\
& \theta=\tan ^{-1}\left[\frac{-B \pm \sqrt{B^{2}-4 A C}}{2 A}\right]
\end{aligned}
$$

Because $\theta$ is determined with a quadratic equation, there will be two values of $\theta$. One value of $\theta$ rotates the parabola so it is symmetrical about the x -axis; the other so it is symmetrical about the y -axis. The required rotation can then be calculated using Equation 10.

$$
\begin{equation*}
\omega=\theta-\gamma \tag{Equation 10}
\end{equation*}
$$

Once the rotation angle is determined, each Modeled $x$ and $y$ point given in the CARS report can then be rotated to the proper alignment using Equation 11. Excel can then plot a best-fit line to the rotated data and give the equation, making the radius of curvature calculation possible.

$$
\begin{align*}
& x^{\prime}=x \cos \omega-y \sin \omega \\
& y^{\prime}=x \sin \omega+y \cos \omega \tag{Equation 11}
\end{align*}
$$

Below are modeled curves and corresponding comparisons of CARS reported radius and radius calculated using the Radius of Curvature equation. These data were collected by ODOT Region 2's Weldon Ryan on Mist-Clatskanie Highway on June 10, 2014. In the first graph of each location, the blue curve is the curve model (Modeled $x$ and $y$ ) given in the CARS report. The green line is the rotated parabola with a best-fit curve and corresponding equation. The second graph shows a comparison between the reported and calculated radius. If the reported radius matches the radius calculated using the radius of curvature equation, these points should form two curves that lay directly on top of each other.

The following results confirm the radius reported by CARS is the radius of curvature at each point $x, y$ along the best-fit parabolic curve model.

## Advisory Speed

With the inclination, speed, and radius modeled through the length of the curve, the speed at which the MUTCD limits will be reached can be calculated for every point on the curve. From the Kinematics section, the superelevation can be calculated using Equation 12 (inclination angle must be converted to radians):

$$
e=100\left[\frac{\left(1.47 V_{c}\right)^{2}}{g R}-f_{D}\right]
$$

Equation 12

Once superelevation is known, the MUTCD side friction limits can be entered as $f_{D}=\tan$ (MUTCD limit) to determine the speed at which the limits will be reached. From the Kinematics section, vehicle speed can be calculated using Equation 13:

$$
V_{c}=\frac{\sqrt{g R\left(f_{D}+\frac{e}{100}\right)}}{1.47}
$$

Equation 13

The minimum calculated advisory speed is the critical speed on the curve - the slowest speed at which the MUTCD limit will be reached. The minimum calculated advisory speed is then rounded down to the nearest 5 mph for posting.

## Interpreting Results

When reading CARS curve reports, the critical output is the average of the minimum calculated
advisory speeds. This is the average speed the side friction limit will be reached. It is important to interpret this speed in the context of MUTCD 2C.08:

Among the engineering practices listed as appropriate for the determination of the recommended advisory speed for a horizontal curve is a traditional ball-bank indicator using the following criteria:

1. 16 degrees of ball-bank for speeds of 20 mph or less
2. 14 degrees of ball-bank for speeds of 25 to 30 mph
3. 12 degrees of ball-bank for speeds of 35 mph and higher.

It is especially important to interpret the average minimum calculated advisory speeds when they are around 30-35 mph and 20-25 mph and choose the MUTCD thresholds appropriately.

In the sample curve report given in Table 2, the minimum calculated advisory speeds for a 12 degree limit are less than 20 mph . For the Northeast direction, the average minimum calculated advisory speed is 19.5 mph . This means if you traveled around the curve at 19.5 mph , the maximum inclination would be 12 degrees. If these results were not checked, this would result in a recommended advisory speed of 15 mph ; however, 12 degrees is the limit for test speeds of 35 mph and greater.

Since 12 degrees is reached at a very slow speed，we can estimate the side friction limit needs to be changed to 16 degrees（limit for speeds 20 and less）．Table 3 shows the results of changing the side friction limit to 16 degrees．

| 6 | Right | South | 99．30\％ | 20.8 mph | 84 ft | 246 ft | $100^{\circ}$ | 9．70\％ | 19.4 mph | 15 mph | 40 ft |

Table 3｜Sample Curve Report－ 16 Degree Threshold

| $\begin{aligned} & \# \\ & \stackrel{\#}{6} \\ & \approx \end{aligned}$ | E |  | 者 |  |  | 5 0 0 0 0 0 0 0 |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | Left | Northeast | 99．3\％ | 20.3 mph | 85 ft | 249 ft | $100^{\circ}$ | 9．50\％ | 21.5 mph | 20 mph | 40 ft |
| 2 | Right | South | 99．2\％ | 20.5 mph | 78 ft | 244 ft | $102^{\circ}$ | 9．80\％ | 21.0 mph | 20 mph | 40 ft |
| 3 | Left | Northeast | 99．5\％ | 20.9 mph | 91 ft | 247 ft | $97^{\circ}$ | 8．20\％ | 22.0 mph | 20 mph | 40 ft |
| 4 | Right | Southeast | 98．6\％ | 20.7 mph | 81 ft | 247 ft | $101^{\circ}$ | 9．70\％ | 21.3 mph | 20 mph | 40 ft |
| 5 | Left | Northeast | 99．5\％ | 21.6 mph | 97 ft | 240 ft | $93^{\circ}$ | 7．30\％ | 22.4 mph | 20 mph | 40 ft |
| 6 | Right | South | 99．3\％ | 20.8 mph | 84 ft | 246 ft | $100^{\circ}$ | 9．70\％ | 21.6 mph | 20 mph | 40 ft |

Setting the side friction limit to 16 degrees，the average minimum calculated advisory speed for the Northeast direction is 22.0 mph ．So at 20 mph ，the MUTCD threshold of 16 degrees will not be exceeded； 20 mph would be the recommended advisory speed．

## Data Gathering

In order to test differences between CARS and the ODOT digital ball-banking spreadsheet, compare CARS results to existing curve signing, and compare sensitivity of CARS results, CARS data and ODOT spreadsheet data were collected by ODOT Region 2's Weldon Ryan on:

- 3 Rivers Highway No. 032 (OR22),
- Oregon Coast Highway No. 009 (US101),
- Cascade Highway No. 160 (OR213), and
- Yamhill-Newberg Highway No. 151 (OR240).

In order to further test sensitivity of CARS results, Weldon collected CARS data on

- Mist-Clatskanie Highway No. 110 (OR47), and
- Siletz Highway No. 181 (OR229).

Weldon used Region 2's 2007 Chevy 2500 HD pickup to gather all data. Inventory of existing advisory signs on OR 22 and US 101 were based on Google Streetview imagery dated October 2013 for both highways. Data comparison results are tabulated in the Appendix.

These corridors were chosen because:

1. There is a high density of horizontal curves,
2. There are a variety of curve types and advisory speeds,
3. Weldon already collected data using the GPS-enabled ODOT spreadsheet on OR 22, US 101, OR 213 , and OR 240, and,
4. There is a variety of terrain and tree coverage where GPS signal could be lost.

## 3 Rivers Highway No. 032 (OR 22)

CARS data were collected on the entire length of 3 Rivers Highway on Thursday June 5 and 6, 2014; four passes in each direction. The first three passes were at or below the existing advisory speeds and were on average within 6 mph of each other. The last pass was done faster than the first three (on average 13 mph faster). After data were collected, 18 curves were chosen along the corridor to see whether different test speeds affect the calculated advisory speed and determine differences in recommended advisory speed between CARS, ODOT spreadsheet, and existing signing. CARS curve reports on OR 22 were generated by Eric Leaming.

ODOT Ball-banking spreadsheet data were collected from MP 00 to MP 21 between April 30 and May 27, 2014.

3 Rivers Highway is classified as a Rural Minor Arterial between Valley Junction (Spirit Mountain Casino) and Hebo in the northwest Oregon Coast Range. This section of highway is narrow and winding along the Little Nestucca River and runs against hillsides and in shallow canyons in sections.

Figure 4 | 3 Rivers Highway

## Oregon Coast Highway No. 009 (US 101)

CARS data were collected on June 6, 2014 from MP 84.9 (Hebo, intersection with OR 22) to MP 67.0 (Tillamook); three passes in each direction. Each pass was at or below the existing advisory speed. CARS curve reports were generated by Ian Roholt.

ODOT Ball-banking spreadsheet data were collected from MP 3 in Astoria to MP 129 south of Depoe Bay. The section of US 101 between Tillamook and Hebo was collected March 11-13, 2014.

This section of the Oregon Coast Highway is classified as a Rural Principal Arterial and winds through cow pastures along the Nestucca River.

Figure 5 | Oregon Coast Highway

## Cascade Highway No. 160 (OR 213)

CARS data were collected on July 17, 2014 along the entire length of Cascade Highway; three passes in each direction. Each pass was at or below the existing advisory speed. CARS curve reports were generated by Ian Roholt.

ODOT Ball-banking spreadsheet data were collected from MP 18.3 to MP 26.1 on April 7, 2014.

Cascade Highway is classified as a Rural Minor Arterial running from Silverton to Oregon City through farm areas in the northern Willamette Valley.

Figure 6 | Cascade Highway

## Yamhill-Newberg Highway No. 151 (OR 240)

CARS data were collected on July 28, 2014 along the entire length of the Yamhill-Newberg Highway; three passes in each direction. Each pass was at or below the existing advisory speed. CARS curve reports were generated by Ian Roholt.

ODOT Ball-banking spreadsheet data were collected from MP 1.6 to MP 11.2 on April 8-9, 2014.

Yamhill-Newberg Highway is a short section classified as a Rural Minor Arterial running about 11 miles from Newberg to Yamhill through farm areas in the northern Willamette Valley.

Figure 7 | Yamhill-Newberg Highway

## Mist-Clatskanie Highway No. 110 (OR 47)

CARS data were collected on June 10, 2014 along the entire length of the Mist-Clatskanie Highway; three passes in each direction. Each pass was at or below the existing advisory speed. CARS curve reports were generated by Ian Roholt.

Mist-Clatskanie Highway is classified as a Rural Major Collector between Mist and Clatskanie in the northwest Oregon Coast Range. This section of highway is mountainous with many sharp turns and steep grades, descending out of the coast range to the Columbia River.

Figure 8 | Mist-Clatskanie Highway

## Siletz Highway No. 181 (OR 229)

CARS data were collected on June 30 and July 1, 2014 along the entire length of the Siletz Highway; three passes in each direction. Each pass was at or below the existing advisory speed. CARS curve reports were generated by Ian Roholt.

Siletz Highway is classified as a Rural Major Collector between Toledo and Lincoln City through the Coast Range and along the Siletz River. There is little to no shoulder the length of the highway with many horizontal curves in small valleys and on hillsides.

Figure 9 | Siletz Highway

## Driving Method

The CARS Instruction Manual [17] says driving should be done as smooth as possible, with the test vehicle in the center of the driving lane. Erratic steering will result in lower recommended curve advisory speeds. Driving should be done at or below the posted speed, and slower is better.

Because momentary jerks of the wheel cause spikes in inclination, the smoother the data are collected the more reliable the data will be, resulting in greater confidence in the correct resulting advisory speed. Driving at slower speeds results in a denser dataset for each curve, which also increases confidence in the calculated results.

## Speed

The CARS Instruction Manual gives the following directions related to speed during data collection:

- Gather data at or below the posted speed limit. Data can be collected at any speed, but more accurate data will be recorded at slower speeds.
- It is not necessary to drive at a speed to achieve the side friction limit, as is the case with the classic Ball Banking technique; slower is better.
- The investigator can come to a stop during the test, but prolonged stops on a curve should be avoided.

Theoretically, as long as the investigator travels through the curve smoothly (e.g. without jerking the wheel causing a spike in lateral acceleration), data can be gathered at any speed since it is used in combination with curve radius and lateral acceleration to calculate superelevation.

To test this, data were gathered on 3 Rivers Highway at different test speeds (see Data Gathering section and the Appendix). From these data, the following can be observed:

- The average difference between the maximum and minimum calculated advisory speed at each curve was 1.6 mph when all four runs were included.
- The average difference between the maximum and minimum calculated advisory speed at each curve was 0.9 mph when only the first three runs were included (similar test speeds).
- The average difference between the calculated advisory speed at each curve for the faster run when compared to the first three slower runs was 1.1 mph .
- The difference between the average and median calculated advisory speeds at each curve was no greater than 0.7 mph when only the first three runs were included (similar test speeds).

To further test if disparity between test speeds affects disparity between calculated advisory speeds when following the recommendations in the CARS Instruction Manual, the standard deviation of average test speeds were compared to the standard deviation of calculated advisory speeds from data gathered on 428 curve approaches on 3 Rivers Highway, Oregon Coast Highway, Mist-Clatskanie Highway, Siletz Highway, Yamhill-Newberg Highway, and Cascade Highway. These data were gathered following the recommendations given in the CARS Instruction Manual; the standard deviation of average test speeds did not exceed 4.5 mph . This comparison is shown in Figure 10, with a red line of best fit plotted through
the data. Because the slope of the best fit line is very close to $0 \mathrm{mph} / \mathrm{mph}$, there is no practical correlation between the disparity of average test speeds and the disparity of calculated advisory speeds.

Figure 10 | Std. Dev. of Calc. Advisory Speed vs. Std. Dev. of Avg. Test Speed

Based on these results, speed does not need to be constant from run to run in order to reach similar calculated advisory speeds. Speed of individual runs should be kept relatively constant in order to drive smoothly and avoid unnecessary spikes in lateral acceleration. Less variance in test speed of individual runs results in less variance in the calculated advisory speeds. Speed can vary from curve to curve; speed while driving through the curve should be kept relatively constant.

Another curve advisory software platform that gathers data in a similar way to CARS calculates superelevation to estimate advisory speed (Texas Curve Advisory Software, TCAS). This system sets a maximum speed for data collection of 45 mph in order to accurately estimate superelevation (standard deviation of calculated superelevation with 0.9 percent or less) and radius. Hence, with the TCAS system, 45 mph is considered an upper limit on test speed when superelevation rate is being measured, with a slower speed desired because it will yield a more accurate estimate [18].

The data collected and the TCAS recommendation support the recommendations in the CARS Instruction Manual - driving should be done as smoothly as practical and slower is better.

## Effect of Different Drivers

Because ODOT will be using different investigators statewide for curve evaluations, and may be using interns who have not had the benefit of years of curve evaluation experience, Region 2 did an ad hoc test of the effect of different drivers. Kellie Tasselli collected CARS data on the entire length of Three Rivers Highway No. 032 on Friday June 6, 2014; one pass in each direction. Weldon Ryan collected multiple runs on the same highway on June 5 and 6,2014. The data are summarized in the Appendix.

Weldon Ryan, Region 2's traffic investigator, is one of the most experienced curve evaluation drivers at ODOT and is likely representative of most experienced investigators after working with CARS for about 1 week. Kellie Tasselli, Region 2's sign designer, had little experience evaluating curves and may be representative of an intern who has been trained by an experienced investigator but has not yet collected data. Weldon discussed proper driving methods to Kellie before the test runs. Weldon was a passenger with Kellie during her test runs but did not coach on driving during data collection.

After data were collected, 10 curves were chosen along the corridor to test whether an experienced investigator and an inexperienced investigator would gather data that would result in similar calculated advisory speeds and the same recommended advisory speeds. One test run in each direction for Weldon was compared with one test run in each direction for Kellie. The results are summarized in Table 6 in the Appendix.

From these 10 test curves ( 20 test runs), the average difference in calculated advisory speed was -0.1 mph , meaning the calculated advisory speed using data Kellie collected was, on average, 0.1 mph higher than the calculated advisory speed using data Weldon collected. This is a small sample size; however, results this close after little training shows promise.

The curves resulting in different recommended advisory speeds had calculated advisory speeds 1.5 to 3.7 mph apart and were straddling the 5 mph rounding increments. Considering the difference of investigator experience, these results show the potential for an inexperienced investigator, if properly trained and with some practice, to achieve similar results to an experienced investigator.

More importantly, these results show the importance of multiple runs in the same direction to further test curves that have calculated advisory speeds very close to the 5 mph rounding increments; when a calculated advisory speed comes to 29.9 mph , the next run could easily be 30.1 mph , which would result in a different recommended advisory speed on the curve report.

## Minimum Number of Runs

While one of the selling points of CARS is being able to calculate advisory speed with one pass in each direction, the same environmental variables at play during traditional ball-banking may affect CARS data (e.g.: driving style, pavement quality, GPS data precision, roadkill in the wheel path, etc.). These introduce some error into the analysis. This error may cause a different recommended advisory speed on curves where the calculated advisory speed could be very close to the 5 mph rounding increments for signing. Multiple runs should help account for some of these variables; however, no guidance is given in the Rieker CARS Instruction manual on minimum number of passes.

Minimum number of runs can be estimated using a statistical sampling size calculation. The sample size required to estimate the true mean $\mu$ with a level of confidence ( $1-\alpha)^{*} 100 \%$, with a specified margin of error $E$, is calculated using Equation 14:

$$
n=\left[\frac{\left(z \frac{a}{2}\right) \sigma}{E}\right]^{2}
$$

## Equation 14

Where sample size, $n$ is rounded up to the nearest whole number.
Ideally, estimating the standard deviation $\sigma$ for this calculation should be based on a sample size of at least 30 passes per curve in order to minimize the margin of error of the standard deviation [19]. Since that level of data gathering was not practical for available investigators' workloads, the true standard deviation needed to be estimated using small sample sizes from a large number of curves. This does not minimize the margin of error for standard deviation but helps determine a conservative standard deviation to apply to the data.

In order to estimate standard deviation of the minimum calculated advisory speed, the standard deviation of three runs were calculated for the 428 curve approaches chosen on the Oregon Coast Highway, 3 Rivers Highway, Mist-Clatskanie Highway, Siletz Highway, Yamhill-Newberg Highway, and Cascade Highway given in the Appendix. Approaches with a calculated advisory speed greater than 55 mph at 12 degrees were not included because 55 mph is the maximum posted speed on these highways and would not be signed with an advisory speed.

There appeared to be a slight correlation between the average calculated advisory speed and standard deviation of the calculated advisory speeds. Higher average advisory speeds may have a slightly greater standard deviation, shown in Figure 11 (the red line is a best-fit line through the data).

Figure 11 | Std. Dev. of Calc. Advisory Speeds vs. Average Calculated Advisory Speed

In order to account for this correlation, the standard deviation was taken as a percent of the average calculated advisory speed, shown in Figure 12. This relationship has practically no correlation, shown in 0 slope in the red best-fit line. The $90^{\text {th }}$ percentile of the percent of calculated advisory speed was then assumed to be a conservative estimate of the true standard deviation ( $\sigma_{90}=3.06 \%$ of calculated advisory speed), shown as the green line.

Figure 12 | Std. Dev. of Calc. Advisory Speed (\%) vs. Avg. Calc. Advisory Speed

It is important to remember this standard deviation is based on data collected by one very experienced investigator (Weldon Ryan) along a select number of winding highways in the Oregon Coast Range and Willamette Valley. Smooth driving while collecting data kept the standard deviation of multiple runs low.

Assuming a normal distribution, $Z \alpha / 2=1.960$ at the $95 \%$ confidence interval [19]. Plugging these values into Equation 14, Figure 13 shows a comparison between margin of error and number of runs at the $95 \%$ confidence interval. A high ( $95 \%$ ) confidence interval should be used because curve advisory speeds will be relied upon by road users for navigation through curves.

Figure 13 | Margin of Error vs. Number of Runs - 95\% Confidence Interval

More confidence in the results requires more runs. Since the rounding increments for signing are 5 mph , the margin of error should be less than $\pm 2.0 \mathrm{mph}$ to keep the error window smaller than the rounding increment. The margin of error for one run is $\pm 6.0 \%$ at the $95 \%$ confidence interval. At very low speeds ( $<25 \mathrm{mph}$ ), this margin of error may be acceptable; however, as speed increases, margin of error increases. A margin of error less than $\pm 2.0 \mathrm{mph}$ can be achieved for speeds up to 57 mph in 3 runs ( $3.5 \%$ error) at the $95 \%$ confidence interval. This means there is a $95 \%$ probability that the true average is $\pm 3.5 \%$ of the average of 3 runs. This percent error should be acceptable on most ODOT highways as advisory speeds should not be greater than 55 mph - less than the $\pm 2.0 \mathrm{mph}$ maximum desirable margin of error.

Recognizing the agency's limited resources for evaluating curves, $\pm 3.5 \%$ of the average calculated advisory speed is a reasonable margin of error that can be achieved in a limited number of runs. Based on this analysis, the average calculated advisory speed of at least 3 runs should be used when determining the final advisory speed. More runs may be used for greater confidence. Using the average gives designers a confidence interval and margin of error to base and defend their judgments on.

## Comparison to Existing Signing

In 2011, Dixon and Avelar [4] studied the effects of changing Oregon's ball-banking limits to the 2009 MUTCD limits. Dixon and Avelar examined 80 state-maintained corridors to see what signing changes would be required statewide if the 2009 MUTCD limits were adopted. They estimated:

- $29 \%$ of curves would not require signing changes,
- $28 \%$ of curves would require sign removal,
- $33 \%$ of curves would require a +5 mph adjustment,
- $6 \%$ of curves would require a -5 mph adjustment, and
- $3.5 \%$ of curves would require $\mathrm{a}+10 \mathrm{mph}$ adjustment.

CARS recommended advisory speeds and ODOT Ball-banking spreadsheet recommended advisory speeds were compared to existing advisory speeds. Data were collected on Oregon Coast Highway 009 (US 101) between OR 22 and Tillamook and Three Rivers Highway 032 (OR 22) (see Data Gathering section). Twenty-eight curves were chosen along these corridors that had signing unique to the curve (not part of a winding road series) for CARS data; 23 curves for ODOT Ball-banking data.

Of the 56 curve approaches compared to existing advisory speeds ( 28 curves, 2 approaches at each), CARS had a recommended advisory of:

- 0 mph difference at 11 approaches ( $20 \%$ )
- 5 mph higher at 29 approaches ( $52 \%$ )
- 10 mph higher at 12 approaches ( $21 \%$ )
- 15 mph higher at 2 approaches ( $4 \%$ )
- 20 mph higher at 2 approaches( $4 \%$ )

Of the 46 curve approaches compared to existing advisory speeds ( 23 curves, 2 approaches at each), ODOT Ball-banking spreadsheet had a recommended advisory of:

- 0 mph difference at 16 approaches ( $35 \%$ )
- 5 mph higher at 24 approaches ( $52 \%$ )
- 10 mph higher at 5 approaches ( $11 \%$ )
- 15 mph higher at 1 approach ( $2 \%$ )

It is important to note existing signing is not a reliable measure of the magnitude of change when applying the new MUTCD limits. Region investigators, county engineers, other state DOTs, and researchers have all reported existing signing is so inconsistent that they are an unreliable measure of actual signing needs. Decades of sign replacements, inconsistent curve evaluation methods, and other related factors have led to the reason why ODOT is going through this exercise in the first place.

## Method Differences

There are many different ways to determine curve advisory speeds. The 2009 MUTCD acknowledges three methods (including ball-banking and accelerometer that provides direct determination of side friction factors). The FHWA Safety Program discusses six methods in their publication Procedures for setting Advisory Speeds on Curves [10]. The different ball-banking methods ODOT has used in the past 5 years each have subtle differences and may result in different advisory speeds at some curves. The limitations of traditional ball-and-vial ball-banking are well known; differences between the ODOT ballbanking spreadsheet and CARS are not as well-known and are discussed here. For a comparison between analog and digital ball-banking devices, see Dixon and Rohani's report Methodologies for Estimating Advisory Curve Speeds on Oregon Highways [3].

## Advisory Speed Recommendations

Recommended advisory speed differences were tested by comparing data collected using the ODOT spreadsheet and CARS on US 101, OR 22, OR 213, and OR 240 (see Data Gathering section and the Appendix). 38 curves were chosen along these corridors to compare ending advisory speed recommendations. Results are tabulated in Table 4 in the Appendix. CARS recommended advisory speeds are the average value of three runs rounded down to the nearest 5 mph .

Of the 76 curve approaches compared ( 38 curves, 2 approaches at each), CARS had a recommended advisory speed of

- 5 mph less than the ODOT spreadsheet at 1 approach ( $2 \%$ )
- 0 mph difference at 38 approaches ( $50 \%$ )
- 5 mph higher than the ODOT spreadsheet at 30 approaches ( $39 \%$ )
- 10 mph higher than the ODOT spreadsheet at 7 approaches ( $9 \%$ )

At the vast majority ( $91 \%$ ) of approaches, CARS and the ODOT spreadsheet recommended advisory speeds within 5 mph of each other; however, when there were differences, CARS tended to recommend advisory speeds greater than the ODOT spreadsheet. The following discussion explores reasons why this may be the case.

## Driving During Data Collection

Driving style during data collection is different between the two systems. Driving using the ODOT spreadsheet is the same as traditional ball-and-vial driving. The investigator needs to travel through the curve multiple times at various speeds to determine the advisory speed. In some locations, the investigator needs to rapidly accelerate or decelerate to get to the run speed, depending on curve spacing, traffic, or safe turn-around location, among other variables. The investigator also needs to set cruise control at the run speed prior to entering the curve - a task not always precise, accurate, nor easily accomplished.

Driving using CARS is more fluid than traditional ball-and-vial driving. The investigator does not need to travel through the curve multiple times to determine an advisory speed (though multiple passes are needed for confidence). The investigator can gather data at any speed without the need to set cruise control, so driving can be more fluid and controlled. This reduces the probability of artificial spikes in
inclination due to the driver. CARS also eliminates the risk of the investigation vehicle not traveling at exactly the correct run speed by simultaneously collecting speed, location, and inclination data.

The small effect of body roll during data collection may also explain differences in recommended advisory speeds. Traditional ball-and-vial driving requires data gathering at the advisory speed, whereas CARS allows for data collection at any speed, but recommended slower than the advisory speed. Faster test speeds introduce more error due to body roll, albeit a small error. As discussed in the Kinematics section, Carlson and Mason [13] estimated if a vehicle with a roll rate of 7 degrees/g (1992 Taurus) were used for a traditional ball-banking investigating and the roll rate was neglected, the estimated safe speed would be 5 to 7 percent less than intended. At high speeds ( $>40 \mathrm{mph}$ ) this error could be at least 2.3 to 3.1 mph ; greater error at higher speeds.

Because CARS allows data collection at slower speeds, inclination is affected less by body roll. This may result in slightly lower inclination measurements, which increases the calculated advisory speed. The magnitude of this affect is likely less than 5 to 7 percent and at the most extreme should affect the posted advisory speed by no more than +5 mph , assuming the vehicle is traveling fast enough to roll to the outside of the curve during data collection.

Based on driving style alone, CARS will likely calculate slightly higher advisory speeds than the ODOT spreadsheet because the driving style during data collection is more fluid and test speeds are slower. Fluid driving is closer to how the public travels through curves than ball-and-vial driving and the error due to body roll is likely less than ball-and-vial driving.

## Post Processing

The ODOT ball-banking spreadsheet and CARS post process gathered data; however, differences in postprocessing may result in different advisory speeds. The digital instruments used in both systems take multiple readings per second and are very sensitive to changes in the road surface; additionally, the CARS GPS is not survey-grade. The ODOT spreadsheet post-processes raw inclination data by developing a weighted moving average, shown in Equation 15 (for more information, see the ODOT spreadsheet instructions page). The spreadsheet cannot develop a best-fit model for curves because it does not know where a curve begins or ends.

$$
S_{t}=\frac{1\left(B B_{t-0.50}\right)+2\left(B B_{t-0.25}\right)+3\left(B B_{t}\right)+2\left(B B_{t+0.25}\right)+1\left(B B_{t+0.50}\right)}{\sum \text { Weights }}
$$

## Equation 15

Where:
$S_{t}=$ Smoothed ball-bank value at time $=\mathrm{t}$ seconds (degrees)
$B B_{t}=$ Raw ball-bank reading for time $=\mathrm{t}$ seconds (degrees)
$t=$ time (seconds)
$\Sigma$ Weights $=$ Sum of the weights as assigned to each $B B_{t}$ value (typically $1+2+3+2+1=9$ )

As discussed in the Variables section, CARS post-processes raw data using best-fit parabolic models for inclination, curve shape, and speed.

Used in this context, best-fit parabolic models will have a greater dampening affect than weighted moving average, meaning CARS can report a lower inclination value than the ODOT spreadsheet on the same curve at the same speed. This can translate to slightly higher calculated advisory speeds than the ODOT spreadsheet method.

## Other Issues

Other questions explored during this investigation included:

- Calculated advisory speed sensitivity to model fit,
- Cross-axis sensitivity,
- Loss of GPS signal, and

## Advisory Sensitivity to Model Fit

The variance between calculated advisory speeds of runs appears to loosely correlate with the percent fit of the selected data. Figure 14 shows a comparison between calculated advisory speed standard deviations and average fit of the curve model for the 428 curve approaches on the selected highways listed in the Data Gathering section. The CARS Instruction Manual says a fit of $96 \%$ or better should be used. Based on these results, a fit of $96 \%$ is acceptable; a better fit appears to result in more precise estimates of advisory speed, with $99 \%$ or better being best.

Figure 14 | Std. Deviation of Calc. Advisory Speed vs. Average Fit

## Cross Axis Sensitivity

While gathering CARS data on Timberline Highway No. 173, Ryan Virgin (Region 1 Traffic) voiced a concern that steep grades may affect inclination measurement because the RDS7-GPS-PRO is a 2 -axis inclinometer (measuring inclination on a plane perpendicular to the vehicle).

Rieker's Joe Caruso responded in an email (dated August 15, 2014) that steep grades will have no measurable impact on the results of an investigated curve:
"The sensor the RDS7-GPS-PRO uses yields less than $0.5 \%$ error at pitch angles up to 30 degrees. That means on a corner at the limit of 12 degree inclination angle, the error would be 0.06 degrees on a $75 \%$ grade up or down. Since the sensor has an overall accuracy of 0.5 degrees over its operational range, a variance of $\pm 0.06$ degrees is not significant. And, driving slower to produce less than the 12 degrees, reduces that small error."

## Loss of GPS Signal

CARS relies on GPS information to determine the speed and location of the investigation vehicle as it travels around a curve. If GPS signal is lost, there will not be enough information to calculate an advisory speed.

If GPS signal is lost, Rieker has recommended returning to the section of highway at a different time of day and/or different time of week. This allows the satellites to rotate to a different orientation, which may improve GPS signal.

As of the date of this white paper, loss of GPS signal has not been a reported issue. The CARS Revisionary Mode was not examined as part of this shakedown. If GPS signal is not attainable after several attempts over several days, reverting to the ODOT Spreadsheet method may be an alternate option to determine advisory speeds.

## Conclusions and Recommendations

Based on the above analysis and findings, the following can be concluded and recommended:

- The CARS methodology uses best-fit models and common design equations from the Green Book and is an acceptable method to determine curve advisory speed.
- CARS and the ODOT spreadsheet recommended advisory speeds are generally within 5 mph of each other. When different, CARS tends to recommend advisory speeds greater than the ODOT spreadsheet, within 5 mph .
- For statewide consistency, all Oregon highways should be evaluated using the CARS methodology.
- An inexperienced investigator can achieve similar results to an experienced investigator if properly trained and with some practice.
- Speed from run to run on the same curve does not need to be constant.
- When driving through a curve, speed should be kept relatively constant to avoid unnecessary spikes in lateral acceleration.
- Greater model fits generally result in more precise estimates of advisory speed. When building curves, strive for a fit of $99 \%$ or better; $96 \%$ or better is adequate.
- The average calculated advisory speed of 3 runs should be used when determining the final advisory speed. If data are collected properly, this average should be within $\pm 3.5 \%$ of the true average at the $95 \%$ confidence level.
- A training class for traffic investigators and sign designers should be developed covering data collection and interpretation for statewide consistency.

## Example Calculation Walk-Through

## Given

The following latitude/longitude, speed, and inclination data from one pass of a CARS investigation at the subject curve. Calculated advisory speed report data is included for comparison.

## Curve Summary

Highway
MP at PC-PT
CARS Data Collection Date

Mist-Clatskanie Highway No. 110 (OR47)
7.58-7.64

June 10, 2014

## Vicinity Map

## Required

Determine the calculated advisory speed at a ball-bank limit of 14 degrees for the northbound direction.

## Solution

## Step 1 - Convert Lat/Long to Northing/Easting relative to the PC

Latitude and longitude coordinates converted to northing and easting using this website:
http://www.latlong.net/lat-long-utm.html. Reading number 9777 is the PC and is set to coordinates 0,0 . Northings and Eastings are given from the website in meters. Excel was used to convert to feet.

Table 10 | Lat/Long Conversion to X and Y

| Number | Time | Latitude | Longitude | Easting | Northing | Coordinate Relative to PC |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  |  | Meters |  | Feet |  |
|  |  |  |  |  |  | $\mathbf{x}$ | y | $\mathbf{x}$ | y |

## Step 2 - Develop Best-Fit Model for $\mathbf{x}$ and $\mathbf{y}$

Plot the x coordinates over time and y coordinates over time and fit a parabolic best-fit line to the data. These parabolic x and y models can be combined to fit the vehicle travel path, shown in Figure 15 to confirm the vehicle path makes sense.

Figure 15 | Raw and Modeled Data over Map

## Step 3 - Develop Radius Equation

Based on 4 points on the modeled curve, rotate the modeled curve so it is symmetrical about the $y$-axis (calculates to 54.14 degrees for this model). This allows Excel to calculate the equation of the line. From this equation, the first and second derivatives can be found, which allows radius at each point along the model to be calculated.

Figure 16 | Rotated Curve Model Coordinates

| Time from PC | Best-Fit Modeled Coordinates |  | Rotated Coordinates |  |
| :---: | :---: | :---: | :---: | :---: |
|  | $\mathbf{x}$ | y | $\mathbf{x}^{\prime}$ | $\mathrm{y}^{\prime}$ |

Radius of Curvature, $R=\frac{\left[1+\left(\frac{d y}{d x}\right)^{2}\right]^{\frac{3}{2}}}{\left|\frac{d^{2} y}{d x^{2}}\right|}$

Where:

$$
\begin{aligned}
& \frac{d y}{d x}=0.0068 x^{\prime}+0.7410 \\
& \frac{d^{2} y}{d x^{2}}=0.0068 \\
& x^{\prime}=x \cos 54.14^{\circ}-y \sin 51.14^{\circ} \\
& x=\text { Modeled curve } x \text { coordinate } \\
& y=\text { Modeled curve } y \text { coordinate }
\end{aligned}
$$

## Step 4 - Develop Inclination Model

Plot inclination data over time and fit a parabolic best-fit line to the data.

| Time from PC | Raw Inclination |
| :---: | :---: |

| 06.20 | 29.1 |
| 06.41 | 29.1 |
| 06.61 | 29.3 |
| 06.81 | 29.3 |
| 07.00 | 29.6 |
| 07.20 | 29.5 |
| 07.41 | 29.6 |

## Step 6 - Calculate Speed at 14 Degrees

From the above best-fit models, the following equations describe the variables needed to calculate superelevation and speed at 14 degrees ( $0.24 \mathrm{ft} / \mathrm{ft}$ ) of inclination, $t$ seconds of travel from the PC. Results are tabulated in Table 11 with the minimum calculated speed highlighted yellow.

Model $X($ feet $)=3.508 t^{2}-42.901 t+2.154$
Model $Y($ feet $)=2.537 t^{2}+13.302 t-0.272$
Radius $($ feet $)=\frac{\left[1+\left[0.0068\left[X \cos \left(54.14^{\circ}\right)-Y \sin \left(54.14^{\circ}\right)\right]+0.7410\right]^{2}\right]^{(3 / 2)}}{0.0068}$
Inclination $($ degrees $)=-0.559 t^{2}+3.254 t+4.946$
Speed $(m p h)=0.181 t^{2}-0.817 t+26.815$
Superelevation, $e=100\left[\frac{\left(1.47 V_{c}\right)^{2}}{g R}-f_{D}\right]$
Advisory Speed, $V_{c}=\frac{\sqrt{g R\left(f_{D}+\frac{e}{100}\right)}}{1.47}$

Table 11 | Calculated Results
